**ABSTRACT:** The wide applicability of zero-knowledge interactive proofs comes from the possibility of using these proofs as subroutines in cryptographic protocols. A basic question concerning this use is whether the (sequential and/or parallel) composition of zero-knowledge protocols is zero-knowledge too. We demonstrate the limitations of the composition of zero-knowledge protocols by proving that the original definition of zero-knowledge is not closed under sequential composition; and that even the strong formulations of zero-knowledge (e.g. black-box simulation) are not closed under parallel execution.

We present lower bounds on the round complexity of zero-knowledge proofs, with significant implications to the parallelization of zero-knowledge protocols. We prove that 3-round interactive proofs and constant-round Arthur-Merlin proofs that are black-box simulation zero-knowledge exist only for languages in BPP. In particular, it follows that the "parallel versions" of the first interactive proofs systems presented for quadratic residuosity, graph isomorphism and any language in NP, are not black-box simulation zero-knowledge, unless the corresponding languages are in BPP. Whether these parallel versions constitute zero-knowledge proofs was an intriguing open question arising from the early works on zero-knowledge. Other consequences are a proof of optimality for the round complexity of various known zero-knowledge protocols, and the necessity of using secret coins in the design of "parallelizable" constant-round zero-knowledge proofs.

## 1. INTRODUCTION

In this paper we investigate the problem of composing zero-knowledge proof systems. Zero-knowledge proof systems, introduced in the seminal paper of Goldwasser, Micali and Rackoff [GMR1], are efficient interactive proofs which have the remarkable property of yielding nothing but the validity of the assertion. Namely, whatever can be efficiently computed after interacting with a zero-knowledge prover, can be efficiently computed on input a valid assertion. Thus, a zero-knowledge proof is computationally equivalent to an answer of a trusted oracle.

A basic question regarding zero-knowledge interactive proofs is whether their composition remains zero-knowledge. This question is not only of theoretical importance, but is also crucial to the utilization of zero-knowledge proof systems as subprotocols inside cryptographic protocols. Of particular interest are sequential and parallel composition. Candidate "theorems" (whose correctness we investigate) are:

*Sequential Composition:* Let  $\Pi_1$  and  $\Pi_2$  be zero-knowledge proof systems for languages  $L_1$  and  $L_2$  respectively. Then, on input  $x_1 \circ x_2$ , executing first  $\Pi_1$  on  $x_1$  and afterwards executing  $\Pi_2$  on  $x_2$ , constitutes a zero-knowledge interactive proof system for  $L_1 \circ L_2$ .

*Parallel Composition:* Let  $\Pi_1$  and  $\Pi_2$  be as above. Then, on input  $x_1 \circ x_2$ , executing concurrently  $\Pi_1$  on input  $x_1$  and  $\Pi_2$  on  $x_2$ , constitutes a zero-knowledge interactive proof system for  $L_1 \circ L_2$ . (Concurrent execution means that the  $i$ -th message of the composed protocol consists of the concatenation of the  $i$ -th messages in  $\Pi_1$  and  $\Pi_2$ , respectively).

### Sequential Composition

Soon after the publication of the [GMR1] paper, several researchers noticed that the formulation of zero-knowledge proposed therein (hereafter referred as the *original* formulation) is probably not closed under sequential composition. In particular, Feige and Shamir [Fei] proposed a protocol conjectured to be a counterexample to the Sequential Composition "Theorem". In this paper we use the ideas of [Fei] and new results on pseudorandom distributions [GK], to prove that indeed the *original formulation of zero-knowledge is not closed under sequential composition*. Our proof is independent of any intractability assumption. It applies to the notion of *computational* zero-knowledge (see Section 2), and uses computationally unbounded provers. (So far no proof exists for the same result with provers limited to polynomial-time, or for statistical or perfect zero-knowledge.)

The reader should be aware that the Sequential Composition Theorem was proven (by Goldreich and Oren [GO, Ore]) for a stronger ("non-uniform") formulation of zero-

knowledge suggested by several authors (cf. [Fei, GMR2, GO, Ore, TW]). The Sequential Composition Theorem is crucial to the utilization of zero-knowledge interactive proofs in cryptographic applications and in particular to the construction of cryptographic protocols for playing any computable game [Yao,GMW2].

### Parallel Composition

Parallel composition of interactive proofs is widely used as a means of decreasing the error probability of proof systems, while maintaining the number of rounds. Of course one would be interested in applying these advantages of parallelism to zero-knowledge protocols as well. Parallelism is also used in multi-party protocols in which parties wish to prove (the same and/or different) statements to various parties concurrently. Unfortunately, we show in this paper a counterexample to the Parallel Composition "Theorem". Namely, we introduce a pair of protocols which are (computational) zero-knowledge with respect to the strongest known definitions (including the non-uniform formulation discussed above and the "black-box simulation" formulation discussed below) yet their parallel composition is not zero-knowledge (not even in the "weak" sense of the original [GMR1] formulation). Also in this case, our proof does not rely on any unproven hypotheses; on the other hand it uses in an essential way the unbounded computational power of the prover and the computational notion of zero-knowledge. Based on intractability assumptions, Feige and Shamir [FS2] show a perfect zero-knowledge protocol with a polynomial-time prover which fails parallel composition. Our results below on 3-round zero-knowledge proofs imply a similar result but our case requires a super-logarithmic number of repetitions while in [FS2] two repetitions suffice.

By the above result we have ruled out the possibility of proving that particular interactive proofs are zero-knowledge by merely arguing that they are the result of parallel composition of various zero-knowledge protocols. But this does not resolve the question whether concrete cases of composed interactive proofs are zero-knowledge. In particular, since the first presentation of the results in [GMR1] and [GMW1] it was repeatedly asked whether the "parallel versions" of the interactive proofs presented for Quadratic Residuosity, Graph Isomorphism and for any language in NP are zero-knowledge.

### Round complexity of zero-knowledge proofs

In this paper we prove a general result concerning the round complexity of zero-knowledge interactive proofs which, in particular, resolves the question of parallelization of the above mentioned protocols. This general result states that *only BPP languages have 3-round interactive proofs which are black-box simulation zero-knowledge*.<sup>1</sup> Since

---

<sup>1</sup> This result applies to interactive proofs in which the prover can convince the verifier of

the parallel versions of the above examples are 3-round interactive proofs (with negligible cheating probability for the prover) it follows that these interactive proofs cannot be proven zero-knowledge using black-box simulation zero-knowledge, unless the corresponding languages are in BPP. This (negative) result is proven for computational zero-knowledge proofs and therefore applies to statistical and perfect zero-knowledge as well.

Loosely speaking, we say that an interactive proof for a language  $L$  is *black-box simulation zero-knowledge* if there exists a (probabilistic polynomial-time) universal simulator which using any (even non-uniform) verifier  $V^*$  as a black box, produces a probability distribution which is polynomially indistinguishable from the distribution of conversations of (the same)  $V^*$  with the prover, on inputs in  $L$ . This definition of zero-knowledge is more restrictive than the original one which allows each verifier  $V^*$  to have a specific simulator  $S_{V^*}$ . Nevertheless, all *known* zero-knowledge protocols are also black-box simulation zero-knowledge. This fact cannot come as a surprise since it is hard to conceive of a way of taking advantage of the full power of the more liberal definition.

It is not plausible that our result could be extended to 4-round interactive proofs since such proofs are known for languages believed to be outside BPP. The protocols for Quadratic Non-Residuosity [GMR1] and Graph Non-Isomorphism [GMW1] are such examples. In addition, zero-knowledge interactive proofs of 5 rounds are known for Quadratic Residuosity and Graph Isomorphism [BMO1], and assuming the existence of claw-free permutations there exist 5-round zero-knowledge interactive proofs for any language in NP [GKa]. Moreover, our results extend to zero-knowledge *arguments*<sup>2</sup>, for which Feige and Shamir [FS] presented (assuming the existence of one-way functions) a 4-round protocol for any language in NP. Our result implies that the round complexity of this protocol is optimal (as long as  $\text{BPP} \neq \text{NP}$ ).

---

accepting a false assertion with only negligible probability. The above mentioned languages have 3-round zero-knowledge interactive proofs in which the prover has a significant (e.g. constant) probability of cheating.

<sup>2</sup> Interactive *arguments* (also known as "computationally sound proofs" and "computationally convincing protocols") differ from an interactive proof system in that the soundness condition of the system is formulated with respect to *probabilistic polynomial-time* provers, possibly with auxiliary input (see [BCC]). Namely, *efficient* provers cannot fool the verifier into accepting an input not in the language, except with negligible probability.

## Constant Round Arthur-Merlin Proofs

When restricting ourselves to Arthur-Merlin interactive proofs, we can extend the above result to any constant number of rounds. We show that *only BPP languages have constant-round Arthur-Merlin proofs which are also black-box simulation zero-knowledge*.

Arthur-Merlin interactive proofs, introduced by Babai [Bab], are interactive proofs in which all the messages sent by the verifier are the outcome of his coin tosses. In other words, the verifier "keeps no secrets from the prover". Our result is a good reason to believe that the only feasible way of constructing constant-round zero-knowledge interactive proofs is to let the verifier use "secret coins". Indeed, the above mentioned constant-round zero-knowledge proofs, as well as the constant round statistical zero-knowledge proofs of [BMO2], use secret coins. Thus, secret coins do help in the zero-knowledge setting. This should be contrasted with the result of Goldwasser and Sipser [GS] which states that Arthur-Merlin interactive proofs are *equivalent* to general interactive proofs (as far as language recognition is concerned). They show that any language having a general interactive proof of  $k$  rounds, has also an Arthur-Merlin proof of  $k$  rounds. Using our result we see that in the zero-knowledge setting such a preservation of rounds (when transforming IP into AM) is not plausible (e.g., Graph Non-Isomorphism).

Our result concerning Arthur-Merlin proofs is tight in the sense that the languages considered above (e.g. Graph Non-Isomorphism, every language in NP) have unbounded (i.e.  $\omega(n)$ -round, for every unbounded function  $\omega:N \rightarrow N$ ) Arthur-Merlin proof systems which are black-box simulation zero-knowledge. In particular, we get that bounded round Arthur-Merlin proofs which are black-box zero-knowledge exist only for BPP, while unbounded round proofs of the same type exist for all PSPACE (if one-way functions exist [IY, B\*, Sha]). That is, while the *finite hierarchy* of languages having black-box zero-knowledge Arthur-Merlin proofs collapses to BPP ( $= \text{AM}(0)$ ), the corresponding *infinite hierarchy* contains all of PSPACE. This implies (assuming the existence of one-way functions) a separation between the two hierarchies.

**Organization:** In Section 2 we outline the definitions of interactive proofs and zero-knowledge, and introduce some terminology and notation used through the paper. Section 3 presents the definitions and results concerning pseudorandom distributions that are used for disproving the composition theorems. In Sections 4 and 5 we present these disproofs for the case of sequential and parallel composition, respectively. Finally, in Section 6 we present the lower bounds on the round complexity of black-box simulation zero-knowledge proofs. We stress that this last section is technically independent from

sections 3,4 and 5, and can be read without going through these sections.

## 2. PRELIMINARIES

The notions of interactive proofs and zero-knowledge were introduced by Goldwasser, Micali and Rackoff [GMR1]. Here, we give an informal outline of these notions. For formal and complete definitions, as well as the basic results concerning these concepts, the reader is referred to [GMR1, GMW1, GMR2].

An *interactive proof* is a two-party protocol in which a computationally unrestricted *prover*,  $P$ , interacts with a probabilistic polynomial-time *verifier*,  $V$ , by exchanging messages. Both parties share a common input  $x$ . At the end of the interaction the verifier computes a predicate depending on this input and the exchanged messages in order to *accept* or *reject* the input  $x$ . Such a protocol, denoted  $\langle P, V \rangle$ , is called an *interactive proof for a language  $L$*  if the following two conditions hold:

*Completeness property:* For any positive constant  $c$  and sufficiently long  $x \in L$ ,  $\text{Prob}(V \text{ accepts } x) > 1 - |x|^{-c}$ .

*Soundness property:* For any positive constant  $c$  and sufficiently long  $x \notin L$ ,  $\text{Prob}(V \text{ accepts } x) < |x|^{-c}$ , no matter how the prover behaves during the protocol.

(The above probabilities are taken over the coin tosses of both the prover and verifier).

In other words we require that on inputs belonging to  $L$  the probability that the prover  $P$  "convinces"  $V$  to accept the common input is almost 1, while on inputs outside  $L$  there is no prover that can fool  $V$  into accepting, except with negligible probability.

*Note:* Notice that we define an interactive proof to have a negligible probability of error. Some authors define this probability to be just a constant (e.g. 1/3). The latter is motivated by the fact that constant error interactive proofs can be converted into negligible error proofs by parallel repetition. However, in the setting of zero-knowledge interactive proofs our results show that such parallel repetition may sacrifice the zero-knowledge property.

An interactive proof in which the *honest* verifier chooses all its messages at random (i.e. with uniform probability over the set of all strings of same length as the message) is called an *Arthur-Merlin* interactive proof [Bab]. That is, in an Arthur-Merlin proof system the only non-trivial computation carried out by the honest verifier is the evaluation of a polynomial-time predicate at the end of the interaction, in order to decide the acceptance or rejection of the input to the protocol. We say that such a verifier uses *public coins*. (Notice that there is no "public coin" restriction on the cheating verifiers).

We say that an interactive proof has  $k$  rounds if there are a total of  $k$  messages (alternately) exchanged between the prover and verifier during the protocol (i.e. we count messages from both parties). In general, the number  $k$  can be a function  $k(|x|)$  of the input length. The notation  $IP(k)$  stands for the class of languages having  $k$ -round interactive proofs, and  $AM(k)$  for languages having  $k$ -round Arthur-Merlin interactive proofs.

An interactive proof is called *zero-knowledge* if on input  $x \in L$  no probabilistic polynomial-time verifier (i.e. one that may arbitrarily deviate from the predetermined program) gains information from the execution of the protocol, except the knowledge that  $x$  belongs to  $L$ . This means that any polynomial-time computation based on the conversation with the prover can be simulated, without interacting with the real prover, by a probabilistic polynomial-time machine ("the simulator") that gets  $x$  as its only input. More precisely, let  $\langle P, V^* \rangle(x)$  denote the probability distribution generated by the interactive machine (verifier)  $V^*$  which interacts with the prover  $P$  on input  $x \in L$ . We say that an interactive proof is *zero-knowledge* if for all probabilistic polynomial-time machines  $V^*$ , there exists a probabilistic expected polynomial time algorithm  $M_{V^*}$  (called the *simulator*) that on inputs  $x \in L$  produces probability distributions  $M_{V^*}(x)$  that are polynomially indistinguishable from the distributions  $\langle P, V^* \rangle(x)$ . (This notion of zero-knowledge is also called *computational zero-knowledge*).<sup>3</sup>

The above formalization of the notion of zero-knowledge is taken from the original paper by Goldwasser, Micali and Rackoff [GMR1]. Later, stronger formulations of zero-knowledge were introduced in which the simulation requirement is extended to deal with stronger verifiers [Fei, GMR2, GO, Ore, TW]. Namely, verifiers with non-uniform properties, e.g. probabilistic polynomial-time verifiers which get an additional *auxiliary-input* tape, or verifiers modeled by polynomial-size circuits.

One further formulation of zero-knowledge is called *black-box simulation zero-knowledge* [GO, Ore]. This formulation differs from the former by requiring the existence of a ("universal") simulator that using any (non-uniform) verifier  $V^*$  as a black-box, succeeds in simulating the  $\langle P, V^* \rangle$  interaction. In other words, there exists a probabilistic expected polynomial time oracle machine  $M$  such that for any polynomial size verifier  $V^*$  and for  $x \in L$ , the distributions  $\langle P, V^* \rangle(x)$  and  $M^{V^*}(x)$  are polynomially indistinguishable.

---

<sup>3</sup> Other definitions were proposed in which it is required that the distribution generated by the simulator is *identical* to the distribution of conversations between the verifier and the prover (*perfect zero-knowledge*), or at least statistically close (*statistical zero-knowledge*). See [GMR2] for further details.

**Remark:** A complete formalization of the notion of black-box simulation zero-knowledge requires dealing with the following technical problem. The simulator uses  $V^*$  as a black-box. This means that the simulator is responsible, during the simulation process, of feeding into the black-box the external parameters that determine the behavior of  $V^*$ . These parameters are the string representing the input to the protocol, the contents of the random tape of  $V^*$ , and the messages of the prover. A problem arises when feeding the random coins used by  $V^*$ . Although the number of coin tosses used by a particular verifier  $V^*$  is bounded by a polynomial, there is no *single* polynomial that bounds this number for *all* possible verifiers. On the other hand, the simulator  $M$  runs (expected) time that is bounded by a specific polynomial. So, how can this simulator manage to feed a verifier requiring more coin tosses than this bound? In [BMO2] this problem is overcome by stating the existence of two random tapes for  $M$ . The first is used in the regular way for  $M$ 's computations. The second can be entirely fed by  $M$  into  $V^*$  in a single step. That is,  $M$  can feed the random coins for the black-box in an "intelligent way" as long as the number of coins does not exceed the time capability of  $M$ , beyond this number it can only feed truly random bits. We stress that this formalization is general enough to include all *known* zero-knowledge proofs.

An alternative solution to the above problem is to have, *for each* polynomial  $p$ , a simulator  $M_p$  which simulates all verifiers  $V^*$  that use at most  $p(|x|)$  random coins on any input  $x$ . Clearly, the running time of the simulator  $M_p$  may depend on the polynomial  $p$  and then the above difficulty is overcome. This second formulation is weaker than the one proposed in [BMO2], but it suffices for the results proved in our paper and therefore adopted here. (In fact our results of Section 6 only require the existence of a simulator that simulates deterministic verifiers, i.e.  $M_p$  with  $p \equiv 0$ ).

Based on the above remark we give our definition of black-box simulation zero-knowledge.

**Definition:** An interactive proof  $\langle P, V \rangle$  is called *black-box simulation zero-knowledge* if for every polynomial  $p$ , there exists a probabilistic expected polynomial time oracle machine  $M_p$  such that for any polynomial size verifier  $V^*$  that uses at most  $p(n)$  random coins on inputs of length  $n$ , and for  $x \in L$ , the distributions  $\langle P, V^* \rangle(x)$  and  $M_p^{V^*}(x)$  are polynomially indistinguishable.

*Note:* The notion of polynomial indistinguishability in the above definition can be formalized based on non-uniform polynomial size distinguishers, or uniform polynomial-time distinguishers which have black-box access to the corresponding  $V^*$ . Our results apply to both formalizations.

**Terminology:** Through this paper we use the term *negligible* for denoting functions that are (asymptotically) smaller than one over any polynomial, and the term *non-negligible* for denoting functions that are greater than one over some fixed polynomial. More precisely, a function  $f$  from nonnegative integers to reals is called *negligible* if for all constants  $c$  and sufficiently large  $n$ ,  $f(n) < n^{-c}$ . The function  $f$  is called *non-negligible* if there exists a constant  $c$  such that for all (sufficiently large)  $n$ ,  $f(n) > n^{-c}$ . (Observe that non-negligible is not the complement of negligible).

**Notation:** We use the notation  $e \in_R S$  for "the element  $e$  is chosen with uniform probability from the set  $S$ ".

### 3. ON EVASIVE AND PSEUDORANDOM SETS

In the demonstration of counterexamples for the "composition theorems" we make use of pseudorandom distributions which have some interesting "evasiveness" properties. These properties and the corresponding proofs are given in [GK] and cited here without proof.

Roughly speaking, a distribution on a set of strings of length  $k$  is *pseudorandom* if this distribution cannot be efficiently (i.e. in time polynomial in  $k$ ) distinguished from the uniform distribution on the set of all strings of length  $k$ . In order to formalize this notion one has to define it in asymptotical terms and refer to collections of distributions (called *pseudorandom ensembles*), rather than single distributions. The notion of a "pseudorandom set" is made precise in the following definition.

**Definition 3.1:** A set  $S \subseteq \{0,1\}^k$  is called  $(\tau(k), \epsilon(k))$ -*pseudorandom* if for any (probabilistic) circuit  $C$  of size  $\tau(k)$  with  $k$  inputs and a single output

$$|p_C(S) - p_C(\{0,1\}^k)| \leq \epsilon(k)$$

where  $p_C(S)$  (resp.  $p_C(\{0,1\}^k)$ ) denotes the probability that  $C$  outputs 1 when given elements of  $S$  (resp.  $\{0,1\}^k$ ), chosen with uniform probability.

Note that a collection of uniform distributions on a sequence of sets  $S_1, S_2, \dots$ , where each  $S_k$  is a  $(\tau(k), \epsilon(k))$ -pseudorandom set, constitutes a pseudorandom ensemble, provided that both functions  $\tau(n)$  and  $\epsilon^{-1}(n)$  grow faster than any polynomial. Therefore, we shall refer to such a sequence of sets as a *pseudorandom ensemble*.

We now present the concept of "evasive sets". Informally, evasiveness means that it is hard, for efficient algorithms, to find strings which belong to these sets.

**Definition 3.2:** Let  $S_1, S_2, \dots$  be a sequence of (non-empty) sets such that for every  $n$ ,  $S_n \subseteq \{0,1\}^{Q(n)}$ , for a fixed polynomial  $Q$ . Such a sequence is called a *polynomially-*

*evasive* (denoted *P-evasive*) ensemble if for any probabilistic polynomial-time algorithm  $A$ , any constant  $c$ , sufficiently large  $n$ , and any  $x \in \{0,1\}^n$

$$\text{Prob}(A(x) \in S_n) < n^{-c}$$

where the probability is taken over the random coins of algorithm  $A$ .

The following theorem states the existence of a  $P$ -evasive ensemble which is also pseudorandom.

**Theorem 3.1** [GK]: There exists a  $P$ -evasive pseudorandom ensemble  $S_1, S_2, \dots$  with  $Q(n)=4n$ . Furthermore, there exists a Turing machine which on input  $1^n$  outputs the set  $S_n$ .

For disproving the parallel composition theorem we shall need a stronger notion of evasiveness. Namely, one which resists also non-uniform algorithms. This definition of evasiveness involves a collection of sets for each length, rather than a single set per length as in the uniform case.

**Definition 3.3:** Let  $Q(\cdot)$  be a polynomial, and for  $n=1,2,\dots$  let  $S^{(n)}$  be a collection of  $2^n$  sets  $\{S_1^{(n)}, \dots, S_{2^n}^{(n)}\}$ , where each  $S_i^{(n)} \subseteq \{0,1\}^{Q(n)}$ . The sequence  $S^{(1)}, S^{(2)}, \dots$  is called a *non-uniform polynomially evasive* (denoted *P/poly-evasive*) ensemble if for any  $c > 0$ , for sufficiently large  $n$  and any (probabilistic) circuit  $C$  of size  $n^c$  (with  $n$  inputs and  $Q(n)$  outputs)

$$\text{Prob}(C(i) \in S_i) < \frac{1}{n^c}$$

where the probability is taken over the random coins of  $C$  and  $i \in \{1, \dots, 2^n\}$ , both with uniform probability.

That is, a sequence  $S^{(1)}, S^{(2)}, \dots$  is a  $P/poly$ -evasive ensemble if any circuit of size polynomial in  $n$ , which gets a randomly selected index of one of the sets in  $S^{(n)}$ , cannot succeed to output an element in that set, except for a negligible probability.

**Remark:** Notice that in the definition of  $P$ -evasive ensembles the (uniform) algorithm trying to hit an element in the evasive set  $S_n$ , gets as input a string  $x$  of length  $n$ , which can be seen as an auxiliary input. The crucial difference between this "uniform" definition and the definition of  $P/poly$ -evasiveness is that in the latter the auxiliary input is allowed to be of any length polynomial in the length of the target strings, while in the former the auxiliary input is properly shorter than the target strings in the set  $S_n$ .

The following theorem states the existence of a  $P/poly$ -evasive ensemble which is composed of pseudorandom sets.

**Theorem 3.2:** There exists a P/poly-evasive ensemble  $S^{(1)}, S^{(2)}, \dots$  with  $Q(n)=4n$ , such that for every  $n$ , each  $S_i^{(n)}$  is a  $(2^{n/4}, 2^{-n/4})$ -pseudorandom set of cardinality  $2^n$ . Furthermore, there exists a Turing machine which on input  $1^n$  outputs the collection  $S^{(n)}$ .

The proof of this theorem is given in the Appendix.

#### 4. SEQUENTIAL COMPOSITION OF ZERO-KNOWLEDGE PROTOCOLS

A natural requirement from the notion of zero-knowledge proofs is that the information obtained by the verifier during the execution of a zero-knowledge protocol will not enable him to extract any additional knowledge from subsequent executions of the same protocol. That is, it would be desirable that the *sequential composition* of zero-knowledge protocols would yield a protocol which is itself zero-knowledge. Such a property is crucial for applications of zero-knowledge protocols in cryptography (for details and further motivation see [GO, Ore]).

We prove that the original definition of (computational) zero-knowledge introduced by Goldwasser, Micali and Rackoff in [GMR1] *is not closed* under sequential composition. Several authors have previously observed that this definition *probably* does not guarantee the robustness of zero-knowledge under sequential composition, and hence have introduced more robust formulations of zero-knowledge [Fei, GMR2, GO, Ore, TW]. But so far, no proof has been given for the claim that computational zero-knowledge (with uniform verifiers) fails sequential composition.

Intuitively, the reason that a zero-knowledge protocol could not be closed under sequential composition is that the definition of zero-knowledge requires that the information transmitted in the execution of the protocol is "useless" for any *polynomial-time computation*; it does not rule out the possibility that a cheating verifier could take advantage of this "knowledge" in a subsequent interaction with the (*non-polynomial time*) prover for obtaining valuable information. This intuition (presented in [Fei]) is the basis of our example of a protocol which is zero-knowledge in a single execution but reveals significant information when composed twice in a sequence. This protocol, presented in the proof of the following theorem, uses a P-evasive ensemble as defined in Definition 3.2 and whose existence is stated in Theorem 3.1.

**Theorem 4.1:** Computational Zero-Knowledge ([GMR1] formulation) is not closed under sequential composition.

**Proof:** Let  $S_1, S_2, \dots$  be a P-evasive pseudorandom ensemble as described in Theorem 3.1. Also, let  $K$  be an (arbitrary) hard Boolean function, in the sense that the language  $L_K = \{x : K(x) = 1\}$  is not in BPP (we use this function as a "knowledge" function).

We present the following interactive-proof protocol  $\langle P, V \rangle$  for the language  $L = \{0,1\}^*$ . (Obviously, this language has a trivial zero-knowledge proof in which the verifier accepts every input, without carrying out any interaction. We intentionally modify this trivial protocol in order to demonstrate a zero-knowledge protocol which fails sequential composition).

Let  $x$  be the common input for  $P$  and  $V$ , and let  $n$  denote the length of  $x$ . The verifier  $V$  begins by sending to the prover a random string  $s$  of length  $4n$ . The prover  $P$  checks whether  $s \in S_n$  (the  $n$ -th set in the P-evasive ensemble defined above). If this is the case (i.e.,  $s \in S_n$ ) then  $P$  sends to  $V$  the value of  $K(x)$ . Otherwise (i.e.,  $s \notin S_n$ ),  $P$  sends to  $V$  a string  $s_0$  randomly selected from  $S_n$ . In any case the verifier accepts the input  $x$  (as belonging to  $L$ ).

We stress that the same P-evasive ensemble is used in all the executions of the protocol. Thus, the set  $S_n$  does not depend on the specific input to the protocol, but only on its length. Therefore, the string  $s_0$ , obtained by the verifier in the first execution of the protocol, enables him to deviate from the protocol during a second execution in order to obtain the value of  $K(x')$ , for any  $x'$  of length  $n$  (and in particular for  $x' = x$ ). Indeed, consider a second execution of the protocol, this time on input  $x'$ . A "cheating" verifier which sends the string  $s = s_0$  instead of choosing it at random, will get the value of  $K(x')$  from the prover. Observe that this cheating verifier obtains information that it could not compute by itself. There is no way to simulate in probabilistic polynomial-time the interaction in which the prover sends the value of  $K(x')$ , otherwise the language  $L_K$  would be in BPP (indeed, such a simulator could be used as a probabilistic polynomial-time algorithm for computing the function  $K$  with negligible error probability. To see that, notice that the real prover in an interaction with the above cheater verifier on inputs  $(x, x')$  will output  $k(x')$  with probability 1. Therefore, the simulator must output the correct value of  $k(x')$  with probability almost 1, or otherwise, its output is polynomially distinguishable from the real conversations). Thus, the protocol is not zero-knowledge when composed twice.

On the other hand, the protocol is zero-knowledge (when executed once). To show this, we present for any verifier  $V^*$ , a polynomial-time simulator  $M_{V^*}$  that can simulate the conversations between  $V^*$  and the prover  $P$ . There is only one message sent by the prover during the protocol. It sends the value of  $K(x)$ , in case that the string  $s$  sent by the verifier belongs to the set  $S_n$ , and a randomly selected element of  $S_n$ , otherwise. By the evasivity condition of the set  $S_n$ , there is only a negligible probability that the first case holds. Indeed, no probabilistic polynomial-time machine (in our case, the verifier) can find such a string  $s \in S_n$ , except with negligible probability (no matter what the input  $x$  to

the protocol is). Thus, the simulator can succeed by always simulating the second possibility, i.e. the sending of a random element  $s_0$  from  $S_n$ . This step is simulated by randomly choosing  $s_0$  from  $\{0,1\}^{4n}$  rather than from  $S_n$ . The indistinguishability of this choice from the original one follows from the fact that each  $S_n$  is a pseudorandom subset of  $\{0,1\}^{4n}$ , and that the prover chooses  $s_0$  from  $S_n$  with uniform probability. ■

**Remark:** The argument presented in the above proof generalizes to any language  $L$  having a zero-knowledge interactive proof. Simply, modify the zero-knowledge proof for  $L$  as in the proof of Theorem 4.1.

**Remark:** Another example of a zero-knowledge protocol which is not closed under sequential composition was independently found by D. Simon [Sim]. His construction assumes the existence of secure encryption systems.

## 5. PARALLEL COMPOSITION OF ZERO-KNOWLEDGE PROTOCOLS

In this section we address the question of whether zero-knowledge interactive proofs are robust under parallel composition.

Clearly, we cannot expect the original GMR definition to satisfy this condition: it is easy to see that a zero-knowledge protocol which is not closed under sequential composition can be transformed into another zero-knowledge protocol which fails parallel composition.

In light of the fact that *auxiliary-input* zero-knowledge is robust under sequential composition [GO, Ore], it is an interesting open question whether this formulation of zero-knowledge is also robust under parallel composition. The main result of this section is that this is *not* the case. We prove the existence of protocols which are zero-knowledge even against non-uniform verifiers (e.g. auxiliary-input zero-knowledge), but which do not remain zero-knowledge when executed twice in parallel. As in the case of sequential composition our results concern only computational zero-knowledge.

The ideas used for the design of a protocol which fails parallel composition are similar to those used for the sequential case. There, we have used the pseudorandomness and evasiveness of some sets to construct the intended protocol. We use this method also here. The main difficulty for extending these properties to the present case, is that now we need an evasive collection which resists even non-uniform verifiers. Clearly, a P-evasive ensemble will not satisfy this condition, since for any set of strings there exist non-uniform verifiers which can output elements in this set (e.g. by getting such a string as auxiliary-input). Instead, we use the notion of P/poly-evasive ensembles as defined in Definition 3.3. Based on Theorem 3.2 that states the existence of such ensembles we

prove the main result of this section:

**Theorem 5.1:** Computational Zero-Knowledge (even with non-uniform verifiers) is not closed under parallel composition.

**Proof:** We present a pair of protocols  $\langle P_1, V_1 \rangle$  and  $\langle P_2, V_2 \rangle$  which are zero-knowledge when executed independently, but whose parallel composition is provably not zero-knowledge.

We use some dummy steps in the protocols in order to achieve synchronization between them. Of course one can modify the protocol substituting these extra steps by significant ones. The version we give here prefers simplicity over naturality. Both protocols consist of five steps and are described below (see also Figure 1).

$P_1$	$V_1$	step	$P_2$	$V_2$
$i \in_R \{1, \dots, 2^n\} \Rightarrow$		1	dummy step	
	dummy step	2		$\leftarrow j \in_R \{1, \dots, 2^n\}$
dummy step		3	$r \in_R S_j^{(n)} \Rightarrow$	
	$\leftarrow s \in_R \{0, 1\}^{4n}$	4		dummy step
if $s \in S_i^{(n)} : K(x) \Rightarrow$		5	dummy step	

Figure 1: protocols  $\langle P_1, V_1 \rangle$  and  $\langle P_2, V_2 \rangle$  with input  $x$ .

The first protocol is denoted  $\langle P_1, V_1 \rangle$ . Let  $x$  be the input to the protocol and let  $n$  denote its length. The protocol uses (for all its executions) a P/poly-evasive ensemble  $S^{(1)}, S^{(2)}, \dots$  with the properties described in Theorem 3.2. It also involves a hard Boolean function  $K$  as in the proof of Theorem 4.1. The prover  $P_1$  begins by sending to  $V_1$  an index  $i \in_R \{1, \dots, 2^n\}$ . After two dummy steps the verifier  $V_1$  sends to  $P_1$  a string  $s \in_R \{0, 1\}^{4n}$ . The prover  $P_1$  checks whether  $s \in S_i^{(n)}$ . If this is the case then it sends to  $V_1$  the value of  $K(x)$ , (otherwise an empty message). This concludes the protocol.

The second protocol  $\langle P_2, V_2 \rangle$  uses the *same* P/poly-evasive ensemble  $S^{(1)}, S^{(2)}, \dots$  as protocol  $\langle P_1, V_1 \rangle$  does. The first step of the protocol is a dummy one. In the second step the verifier  $V_2$  sends to  $P_2$  an index  $j \in_R \{1, \dots, 2^n\}$ . The prover  $P_2$  responds with a string  $r \in_R S_j^{(n)}$ . After two more dummy steps the protocol stops.

We show that each of the above protocols is indeed zero-knowledge (even for non-uniform verifiers). For the first protocol, there are two steps of the prover to be

simulated. In the first step  $P_1$  sends an index  $i \in_R \{1, \dots, 2^n\}$ . The simulator does the same. In the second step, the prover sends the value of  $K(x)$  *only* if the verifier succeeds to present him a string which belongs to the set  $S_i^{(n)}$ . By the evasivity condition of the sequence  $S^{(1)}, S^{(2)}, \dots$ , this will happen with negligible probability and therefore the simulator can always simulate this step as for the case where the verifier sends a string  $s \notin S_i^{(n)}$ . (Observe that the circuits in the definition of P/poly-evasive ensembles only get as input the index of the set to be hit. Nevertheless, in our case the circuits also have an additional input  $x$ . Clearly, this cannot help them finding an element in  $S_i^{(n)}$ , otherwise, circuits which have such a string incorporated will contradict the evasiveness condition).

In the second protocol,  $\langle P_2, V_2 \rangle$ , the only significant step of the prover  $P_2$  is when it sends an element  $r \in_R S_j^{(n)}$  in response to the index  $j$  sent by the verifier. In this case the simulator will send a string  $r' \in_R \{0, 1\}^{4n}$ . Using the pseudorandomness property of the set  $S_j^{(n)}$  we get that the simulator's choice is polynomially indistinguishable from the prover's one.

Finally we show that the parallel composition of the above protocols into a single protocol  $\langle P, V \rangle$  is not zero-knowledge. Let  $V^*$  be a "cheating" verifier which behaves as follows. Instead of sending a randomly selected index  $j$  (corresponding to the second step of the subprotocol  $\langle P_2, V_2 \rangle$ ) it sends the index  $i$  received from  $P$  as part of  $P_1$ 's first step. Thus,  $j=i$ , and the prover  $P$  will respond with a string  $r \in S_i^{(n)}$ . In the next step this string  $r$  will be sent by  $V^*$  to  $P$  instead of the "random" string  $s$  that  $V_1$  should send to  $P_1$ . The prover  $P$  will verify that  $r \in S_i^{(n)}$  and then will send the information  $K(x)$ . By the hardness of the function  $K$  this step cannot be simulated by a probabilistic polynomial-time machine. Therefore, the composed protocol  $\langle P, V \rangle$  is not zero-knowledge. ■

**Remark:** The two protocols  $\langle P_1, V_1 \rangle$  and  $\langle P_2, V_2 \rangle$  can be merged into a single zero-knowledge protocol which is not robust under parallel composition. In this merged protocol, the verifier chooses (at random) an index  $i \in \{1, 2\}$ , sends it to the prover, and then both parties execute the protocol  $\langle P_i, V_i \rangle$ . When executing two copies of this protocol in parallel, the verifiers may choose  $i=1$  and  $i=2$ , respectively, thus forcing a parallel execution of  $\langle P_1, V_1 \rangle$  and  $\langle P_2, V_2 \rangle$ , which we have shown not to be zero-knowledge.

## 6. ON THE ROUND COMPLEXITY OF ZERO-KNOWLEDGE PROOFS

In this section we present lower bounds on the round complexity of black-box simulation zero-knowledge interactive proofs. We show that only languages in BPP have constant-round Arthur-Merlin interactive proofs which are *black-box simulation zero-knowledge*. (For a definition of black-box simulation zero-knowledge and Arthur-Merlin

interactive proofs see Section 2). We have the following theorem.

**Theorem 6.1:** A language  $L$  has a constant-round Arthur-Merlin interactive proof which is black-box simulation zero-knowledge if and only if  $L \in \text{BPP}$ .

In section 6.1 we present a proof for a special case of this theorem, namely, for the case of a three-round Arthur-Merlin protocol. The general case is proved in section 6.2 using careful extensions of the ideas presented for this special case.

The three-round case can also be extended to general interactive proof systems. That is, we also have the following theorem, proved in section 6.3.

**Theorem 6.2:** A language  $L$  has a three-round interactive proof which is black-box simulation zero-knowledge if and only if  $L \in \text{BPP}$ .

(We remark that [GO, Ore] show that two-round (auxiliary-input) zero-knowledge proofs - not necessarily black-box simulation - exist only for BPP languages).

Our results are optimal in the sense that there exist Arthur-Merlin interactive proofs, for languages believed to be outside BPP, with unbounded number of rounds and which are black-box simulation zero-knowledge. Similarly, there exist four-round interactive proof protocols (using private coins) which are also black-box simulation zero-knowledge. For further details about these protocols, and some consequences concerning the hierarchy of languages having zero-knowledge Arthur-Merlin proofs, see Section 1.

It is interesting to note that our results hold also for a weaker notion of black-box simulation zero-knowledge. Namely, one which only requires the existence of a black-box simulator which succeed in simulating conversations with *deterministic* (non-uniform) verifiers. The sufficiency of this condition follow from the proofs below. Also, the formulation of the completeness condition of an interactive proof (see Section 2) can be relaxed in the following way. We have defined the completeness condition by requiring that the prover can convince the verifier of accepting an input in the language with probability almost 1 (i.e. 1 minus a negligible fraction). For the correctness of our results it suffices to require just a non-negligible probability. (In this section we use this weaker formulation of the completeness condition). On the other hand, the requirement of a negligible probability of convincing the verifier to accept an input not in the language (the soundness condition) is essential. (For example, 3-round zero-knowledge protocols exist for all languages in NP, if the soundness condition is formulated with probability  $\frac{1}{2}$  [GMW1]). Finally, our results hold also in the setting of *interactive arguments* [BCC], i.e. "interactive proofs" in which the prover is limited to probabilistic polynomial-time computations, possibly getting an auxiliary input.

### 6.1 The case AM(3)

**The protocol  $\langle P, V \rangle$ :** Consider an Arthur-Merlin protocol  $\langle P, V \rangle$  for a language  $L$ , consisting of three rounds. We use the following notation. Denote by  $x$  the input for the protocol, and by  $n$  the length of this input. The first message in the interaction is sent by the prover. We denote it by  $\alpha$ . The second round is for  $V$  which sends a string  $\beta$ . The third (and last) message is from  $P$  and we denote it by  $\gamma$ . The predicate computed by the verifier  $V$  in order to accept or reject the input  $x$  is denoted by  $\rho_V$ , and we consider it, for convenience, as a deterministic function  $\rho_V(x, \alpha, \beta, \gamma)$ . (For the general case see Remark 6.2). We will also assume, without loss of generality, the existence of a polynomial  $l(n)$  such that  $|\alpha| = |\beta| = l(n)$ .

**The simulation process:** Let this three-round Arthur-Merlin protocol  $\langle P, V \rangle$  be black-box simulation zero-knowledge. Denote by  $M$  the guaranteed probabilistic expected polynomial-time black-box simulator which given access to the black-box  $V^*$  simulates  $\langle P, V^* \rangle$ . The process of simulation consists of several "tries" or calls to the interacting verifier  $V^*$  ("the black-box"). In each such call the simulator  $M$  feeds the arguments for  $V^*$ . These arguments are the input  $y$  (which may be different from the "true" input  $x$ ), the random coins for  $V^*$ , and a string  $\alpha$  representing the message sent by the prover  $P$ . In our case, it suffices for our results to consider a simulator that is just able to simulate conversations with *deterministic (non-uniform) verifiers*. In particular, this simulator does not care about feeding the black-box  $V^*$  with random coins. This simplifies our proof by avoiding any reference to these random coins for  $V^*$ , and strengthen our result (since it holds even under the sole existence of this weak kind of simulator).

After completing its tries the simulator outputs a conversation  $(y, \alpha, \beta, \gamma)$ .

We shall make some further simplifying assumptions on the behavior of the simulator  $M$ , which will not restrict the generality. In particular, we assume that some cases, which may arise with only negligible probability, do not happen at all. This cannot significantly effect the success probability of the simulator. In other words, any black-box simulator which successfully simulates  $\langle P, V^* \rangle$  conversations of deterministic verifiers  $V^*$  can be changed into another simulator for which the following conventions hold and has a the same success probability as the original simulator, except for a possibly negligible difference. We assume that

- the conversations output by  $M$  have always the form  $(x, \alpha, \beta, \gamma)$ , i.e.  $y = x$ , and that the string  $\beta$  equals the message output by  $V^*$  when fed with inputs  $x$  and  $\alpha$ . Note that these conditions always hold for the real conversations generated by the prover  $P$  and the (deterministic) verifier  $V^*$ . Therefore, the simulator must almost always do

the same. (Otherwise, a distinguisher which has access to  $V^*$ , would distinguish between the simulator's output and the original conversations).

- the simulator  $M$  explicitly tries, in one of its calls to  $V^*$ , the arguments  $x$  and  $\alpha$  appearing in the output conversation. (For example, once the simulator decides on the output conversation with a specific parameter  $\alpha$ , it explicitly feeds  $V^*$  with  $x$  and this value of  $\alpha$  - regardless of whether it asked  $\alpha$  before or not. In any case the answer of the deterministic  $V^*$  to the pair  $(x, \alpha)$  will be always the same).
- the simulator runs (strictly) polynomial-time. (In Remark 6.1 below we show how to handle the general case in which the simulator runs *expected* polynomial-time). We denote by  $t(n)$  a polynomial bounding the number of calls tried by  $M$  before outputting a conversation.

**The simulator as a subroutine:** Our goal is to present a BPP algorithm for the language  $L$ . The idea is to use the simulator  $M$  in order to distinguish between inputs in and outside  $L$ . For that, we use the simulator itself as a subroutine of the algorithm. We do not make any assumption on the internal behaviour of this simulator, but just use the following observation. *The behavior of the simulator  $M$ , interacting with a verifier  $V^*$ , is completely determined by the input  $x$ , the random tape  $R_M$  used by  $M$  and the strings output by  $V^*$  (in response to the arguments fed by the simulator during its tries).* Therefore, in order to operate  $M$ , we just need to feed it with an input  $x$ , a tape of random coins, and a sequence of responses to its messages  $\alpha$ . Below we formally describe a computation process that uses  $M$  as a subroutine. (We stress that in this process there is no *explicit* verifier present).

Fix an input  $x$  of length  $n$ , a string  $R_M$  (of length  $q(n)$ , where  $q(\cdot)$  is a polynomial bounding the number of random coins used by  $M$  on inputs of length  $n$ ) and  $t = t(n)$  (arbitrary) strings  $\beta^{(1)}, \beta^{(2)}, \dots, \beta^{(t)}$ , each of length  $l(n)$ . Activate  $M$  on input  $x$  with its random tape containing  $R_M$ . For each  $y$  and  $\alpha$  tried by  $M$ , respond with a message  $\beta$  from the above list  $\beta^{(1)}, \beta^{(2)}, \dots, \beta^{(t)}$  according to the following rule. (This rule depends on the strings  $\alpha$  but not on  $y$ ). To the first  $\alpha$  presented by  $M$  respond with  $\beta^{(1)}$ . For subsequent  $\alpha$ 's check whether the same string  $\alpha$  was presented before by  $M$ . If so, respond with same  $\beta$  as in that case, if it is the first time this  $\alpha$  is presented then respond with the first unused  $\beta^{(i)}$  in the list. That is, if  $\alpha$  is the  $i$ -th *different* string presented by  $M$  then we respond with  $\beta^{(i)}$ . We denote the  $i$ -th different  $\alpha$  by  $\alpha^{(i)}$ . Clearly,  $\alpha^{(i)}$  is uniquely determined by  $x, R_M$  and the  $i-1$  strings  $\beta^{(1)}, \dots, \beta^{(i-1)}$ , i.e., there exists a deterministic function  $\alpha_M$  such that  $\alpha^{(i)} = \alpha_M(x, R_M, \beta^{(1)}, \dots, \beta^{(i-1)})$ . We denote by  $conv_M(x, R_M, \beta^{(1)}, \dots, \beta^{(t)}) = (x, \alpha, \beta, \gamma)$ , the conversation output by the simulator  $M$  when activated with these parameters (notice that  $t$  strings  $\beta^{(i)}$  always suffice for answering all tries of  $M$ ). By our convention on the

simulator  $M$ , there exists  $i$ ,  $1 \leq i \leq t$  such that  $\alpha = \alpha^{(i)}$  and  $\beta = \beta^{(i)}$ .

**Definition:** We say that a vector  $(x, R_M, \beta^{(1)}, \dots, \beta^{(t)})$  is  $M$ -good if  $\text{conv}_M(x, R_M, \beta^{(1)}, \dots, \beta^{(t)})$  is an accepting conversation for the (honest) verifier  $V$ . Namely, if  $\text{conv}_M(x, R_M, \beta^{(1)}, \dots, \beta^{(t)}) = (x, \alpha, \beta, \gamma)$  and  $\rho_V(x, \alpha, \beta, \gamma) = \text{ACCEPT}$ . We say that  $(x, R_M, \beta^{(1)}, \dots, \beta^{(t)})$  is  $(M, i)$ -good (or  $i$ -good for shortness) if it is  $M$ -good and  $\alpha = \alpha^{(i)}$ ,  $\beta = \beta^{(i)}$ .

The main property of  $M$ -good strings is stated in the following Lemma.

**Lemma 6.3:** Let  $\langle P, V \rangle$  be a 3-round Arthur-Merlin protocol for a language  $L$ . Suppose  $\langle P, V \rangle$  is black-box simulation zero-knowledge, and let  $M$  be a black-box simulator as above. Then,

- (1) For strings  $x$  outside  $L$ , only a negligible portion of the vectors  $(x, R_M, \beta^{(1)}, \dots, \beta^{(t)})$  are  $M$ -good.
- (2) For strings  $x$  in  $L$  there exists a non-negligible portion of the vectors  $(x, R_M, \beta^{(1)}, \dots, \beta^{(t)})$  that are  $M$ -good.

(This non-negligible portion is at least one half of the completeness probability of the protocol  $\langle P, V \rangle$ , i.e. the probability that  $P$  convinces  $V$  to accept  $x$ ).

Before proving this key lemma, we use it to prove Theorem 6.1 for the case of three-round Arthur-Merlin interactive proof.

**Proof of Theorem 6.1 (for the case AM(3)):** By Lemma 6.3 we get the following BPP algorithm for the language  $L$ . On input  $x$ :

- \* select at random a vector  $(R_M, \beta^{(1)}, \dots, \beta^{(t)})$ .
- \* accept  $x$  if and only if  $(x, R_M, \beta^{(1)}, \dots, \beta^{(t)})$  is  $M$ -good.

The complexity of this algorithm is as the complexity of testing for  $M$ -goodness. The later is polynomial-time since it involves running the simulator  $M$  which is polynomial-time, and evaluating the predicate  $\rho_V$  which is also polynomial-time computable. The success probability of the algorithm is given by Lemma 6.3. ■

**Proof of Lemma 6.3:**

**Part (1):** Assume that the portion of  $M$ -good vectors  $(x, R, \beta^{(1)}, \dots, \beta^{(t)})$  for  $x$ 's not in  $L$  is not negligible. This means that there exist infinitely many  $x \notin L$  for which the portion of  $M$ -good vectors is non-negligible. For each such  $x$ , there exists an index  $i_0$ ,  $1 \leq i_0 \leq t$ , for which a non-negligible fraction of the vectors  $(x, R, \beta^{(1)}, \dots, \beta^{(t)})$  are  $i_0$ -good (since there are only polynomially many possible values for  $i_0$ ). Thus, there exists a non-negligible number of prefixes  $(x, R, \beta^{(1)}, \dots, \beta^{(i_0-1)})$ , each with a non-negligible number of  $i_0$ -good continuations  $(\beta^{(i_0)}, \dots, \beta^{(t)})$  (i.e., such that  $(x, R, \beta^{(1)}, \dots, \beta^{(i_0-1)}, \beta^{(i_0)}, \dots, \beta^{(t)})$  are  $i_0$ -

good). Let  $(x, R, \beta^{(1)}, \dots, \beta^{(i_0-1)})$  be such a prefix, and let  $\alpha^{(i_0)} = \alpha_M(x, R, \beta^{(1)}, \dots, \beta^{(i_0-1)})$ .

For each  $i_0$ -good continuation  $(\beta^{(i_0)}, \dots, \beta^{(t)})$  machine  $M$  outputs a conversation  $(x, \alpha^{(i_0)}, \beta^{(i_0)}, \gamma)$  for which  $\rho_V(x, \alpha^{(i_0)}, \beta^{(i_0)}, \gamma) = ACCEPT$ . In particular, there exists a non-negligible number of  $\beta^{(i_0)}$  for which this happens.

In other words, for each  $x$  as above there exists a string  $\alpha_x (= \alpha^{(i_0)})$  for which the set  $B(x, \alpha_x) = \{\beta : \exists \gamma, \rho_V(x, \alpha_x, \beta, \gamma) = ACCEPT\}$  is of non-negligible size among all possible strings  $\beta$ . Consider now a ("cheating") prover that sends this  $\alpha_x$  as its first message. If  $V$  responds with  $\beta \in B(x, \alpha_x)$ , the prover sends the corresponding  $\gamma$  that convinces  $V$  to accept. Since  $V$  selects its messages  $\beta$  at random, then the probability of being convinced by the above prover is (at least) as the relative size of  $B(x, \alpha_x)$ , i.e. non-negligible. Concluding, we have shown the existence of a prover that for infinitely many  $x$ 's outside  $L$ , convinces  $V$  to accept with non-negligible probability. This contradicts the soundness condition of the protocol  $\langle P, V \rangle$ , and this part of the Lemma follows.

Part (2): We show that for strings  $x$  in  $L$  a non-negligible portion of the vectors  $(x, R_M, \beta^{(1)}, \dots, \beta^{(t)})$  are  $M$ -good. We do it by considering the behavior of the simulator  $M$  when receiving "random like" responses from the verifier. This behaviour is analyzed by introducing a particular family of "cheating" verifiers, each of them associated to a different hash function from a family of  $t(n)$ -wise independent hash functions. The  $t(n)$ -wise independence (where  $t(n)$  is the bound on the number of simulator's tries) achieves the necessary randomness from the verifiers responses.

Let  $x \in L$  and let  $n$  denote its length. Consider a family of hash functions  $H_n$  which map  $l(n)$ -bit strings into  $l(n)$ -bit strings, such that the locations assigned to the strings by a randomly selected hash function are uniformly distributed and  $t(n)$ -wise independent. (Recall that  $l(n)$  is the length of messages  $\alpha$  and  $\beta$  in the Arthur-Merlin protocol  $\langle P, V \rangle$  for  $L$ , while  $t(n)$  is the bound on the number of  $M$ 's tries). For properties and implementation of such functions see e.g. [Jof, WC, CG]; in particular, we observe that such functions can be described by a string of length  $t(n) \cdot l(n)$ , i.e. polynomial in  $n$ .

For each hash function  $h \in H_n$  we associate a (deterministic non-uniform) verifier  $V_h^*$ , which responds to the prover's message  $\alpha$  with the string  $\beta = h(\alpha)$  ( $V_h^*$  has wired in the description of  $h$ ). Consider the simulation of  $\langle P, V_h^* \rangle$  conversations by the simulator  $M$ . Fixing an input  $x$ , a random tape  $R_M$  for  $M$ , and a function  $h \in H_n$ , the whole simulation is determined. In particular, this (uniquely) defines a sequence of  $\alpha$ 's tried by the simulator, and the corresponding responses  $\beta$  of  $V_h^*$ . We denote by  $\alpha^{(1)}, \alpha^{(2)}, \dots, \alpha^{(s)}$ , the *different* values of  $\alpha$  in these tries. In case that  $s < t$ , we complete this sequence to  $\alpha^{(1)}, \dots, \alpha^{(s)}, \alpha^{(s+1)}, \dots, \alpha^{(t)}$ , by adding  $t-s$  strings  $\alpha$  in some canonical way, such that

the resultant  $\alpha^{(1)}, \dots, \alpha^{(t)}$  are all different. Let  $\beta^{(i)} = h(\alpha^{(i)})$ ,  $1 \leq i \leq t$ , and define  $v(x, R_M, h) = (x, R_M, \beta^{(1)}, \dots, \beta^{(t)})$ . Part (2) of the lemma follows from the following two claims.

Claim 1: For  $x \in L$ , there is a non-negligible portion of the pairs  $(R_M, h)$  for which the vector  $v(x, R_M, h)$  is  $M$ -good.

Proof: For any input  $x$  to the protocol  $\langle P, V \rangle$ , let  $p_x$  denote the probability that the prover  $P$  convinces  $V$  (the honest verifier) to accept  $x$ . In other words,  $p_x$  is the probability, over the coin sequences  $R_P$  of the prover  $P$ , and (random) choices  $\beta$  of  $V$ , that the resultant conversation  $(x, \alpha(x, R_P), \beta, \gamma(x, R_P, \beta))$  is accepting. By the completeness property of the protocol  $\langle P, V \rangle$ , we get that for  $x$ 's in  $L$  the probabilities  $p_x$  are non-negligible.

Let  $x \in L$  and consider the interaction between the real prover  $P$  and the verifiers  $V_h^*$  on the input  $x$ . Each coin sequence  $R_P$  determines the message  $\alpha$ , and the corresponding response  $h(\alpha)$  by  $V_h^*$ . By the uniformity property of the family  $H_n$  we get that for every  $\alpha$ , all  $\beta$ 's are equi-probable as the result of  $h(\alpha)$ . Therefore, the probability that  $P$  and  $V_h^*$  (for  $h$  uniformly chosen from  $H_n$ ) output an accepting conversation is exactly the same as the probability,  $p_x$ , that  $P$  and  $V$  output such a conversation.

Finally, since the simulator  $M$  succeeds in simulating  $\langle P, V_h^* \rangle$  conversations for all functions  $h \in H_n$ , we get that for each  $h$  the probability that  $M$  outputs an accepting conversation when interacting with  $V_h^*$  is almost the same (up to a negligible difference) as the probability that  $P$  and  $V_h^*$  output an accepting conversation. This last probability, for  $h \in_R H_n$ , is  $p_x$ . We conclude that the probability, over random  $R_M$  and  $h$ , that  $v(x, R_M, h)$  is  $M$ -good is almost  $p_x$ , and thus non-negligible. The claim follows.  $\square$

Claim 2: For all strings  $x$  and  $R_M$ , and for  $h$  chosen with uniform probability from  $H_n$ , the vector  $v(x, R_M, h)$  is uniformly distributed over the set  $\{(x, R_M, \beta^{(1)}, \dots, \beta^{(t)}) : \beta^{(i)} \in \{0, 1\}^{l(n)}\}$

Proof: Recall the function  $\alpha_M$  introduced above. Observe that

$$v(x, R_M, h) = (x, R_M, \beta^{(1)}, \dots, \beta^{(t)})$$

if and only if for every  $i$ ,  $1 \leq i \leq t$ ,

$$h(\alpha_M(x, R_M, \beta^{(1)}, \dots, \beta^{(i-1)})) = \beta^{(i)}.$$

On the other hand, by the uniformity and  $t(n)$ -independence property of the family  $H_n$ , we have that for any  $t$  different elements  $a_1, \dots, a_t$  in the domain of the functions  $h \in H_n$ , the sequence  $h(a_1), \dots, h(a_t)$  is uniformly distributed over all the possible sequences  $b_1, \dots, b_t$  for  $b_i$  in the range of the functions  $H_n$ .

Thus, for all strings  $x$  and  $R_M$ , and for fixed  $\beta^{(1)}, \dots, \beta^{(t)}$ , the probability (for  $h \in_R H_n$ ) that  $v(x, R_M, h) = (x, R_M, \beta^{(1)}, \dots, \beta^{(t)})$  equals the probability that for every  $i$ ,  $1 \leq i \leq t$ ,  $h$  maps  $\alpha^{(i)} = \alpha_M(x, R_M, \beta^{(1)}, \dots, \beta^{(i-1)})$  into  $\beta^{(i)}$ . Since, by definition, all  $\alpha^{(i)}$ 's are different, then we can use the above property of the family  $H_n$  to get that the latter probability is the same for every sequence  $\beta^{(1)}, \dots, \beta^{(t)}$  (i.e. we put  $a_i = \alpha^{(i)}$  and  $b_i = \beta^{(i)}$ ). The claim follows.  $\square$

Claim 2 states that for any  $R_M$ , the value of  $v(x, R_M, h)$  is uniformly distributed over all possible vectors  $(x, R_M, \beta^{(1)}, \dots, \beta^{(t)})$ . On the other hand, by Claim 1, a non-negligible portion of  $v(x, R_M, h)$  are  $M$ -good, and then we get that a non-negligible portion of the vectors  $(x, R_M, \beta^{(1)}, \dots, \beta^{(t)})$  are  $M$ -good.

The Lemma follows.  $\blacksquare$

**Remark 6.1** (*expected polynomial-time simulator*): For simplicity we have assumed that the given simulator,  $M$ , for the protocol  $\langle P, V \rangle$  runs in (strictly) polynomial-time. Nevertheless, in the definition of zero-knowledge we allow this simulator to run *expected* polynomial-time. We show that our results hold also in this general case by transforming a given expected polynomial-time simulator  $M$  into a strictly polynomial-time simulator  $M'$ , and showing that Lemma 6.3 holds for this new simulator. Then, we can use the modified simulator  $M'$  in the BPP algorithm for the language  $L$ .

The simulator  $M'$  behaves as  $M$ , but its running time is truncated after some (fixed) polynomial number of steps, denoted  $s(n)$ . We show how to choose this polynomial  $s(n)$ . Let  $T(n)$  be a polynomial bounding the *expected* running time of  $M$ , and let  $p(n)$  be a (lower) bound on the probability that the prover  $P$  convinces the (honest) verifier  $V$  to accept an input in  $L$  of length  $n$ . We define  $s(n)$  to be  $2 \cdot T(n)/p(n)$ . Since  $1/p(n)$  is polynomially bounded (by the completeness condition of the protocol  $\langle P, V \rangle$ ), then  $s(n)$  is polynomially bounded. With this modification of  $M$  the proof of Lemma 6.3 remains valid, except for a more delicate argument in the proof of Claim 1. The required changes follow.

In that proof we claimed that "for each  $h$  the probability that  $M$  outputs an accepting conversation when interacting with  $V_h^*$  is almost the same (up to a negligible difference) as the probability that  $P$  and  $V_h^*$  output an accepting conversation". This is true for the original simulator  $M$ , but not necessarily for  $M'$ . Since we cut the running of  $M$  after  $s(n)$  steps, then there exist cases in which  $M'$  does not complete the original behavior of  $M$ . Nevertheless, by the choice of  $s(n)$ , the probability (over the coin tosses of  $M'$ ) that this happens (i.e. the running time of  $M$  exceeds  $s(n)$ ) is at most  $p(n)/2$ . Thus, for any  $h$ , the probability that the truncated simulator,  $M'$ , outputs an accepting conversation when interacting with  $V_h^*$  differs from the probability that  $P$  and  $V_h^*$  output an accepting conversation by at most  $p(n)/2$ . For  $h \in_R H_n$ , this last probability was shown (in the original

proof of Claim 1) to be at least  $p(n)$ , and then we get that the probability, over random  $R_{M'}$  and  $h$ , that  $v(x, R_{M'}, h)$  is  $M'$ -good is (up to a negligible difference) larger than  $p(n)/2$ , and then non-negligible. Therefore, Claim 1 follows also in this case.  $\square$

**Remark 6.2** (*randomized  $\rho_V$* ): We have assumed that the only coin tosses of the (honest) verifier  $V$  during the Arthur-Merlin protocol  $\langle P, V \rangle$  are the bits corresponding to the string  $\beta$  sent to the prover, and that no additional coin tosses are used in order to compute the accepting/rejecting predicate  $\rho_V$ . This restriction can be removed from the above proof by using finer arguments as done in our treatment of the general IP(3) case (Section 6.3).

More generally, any  $AM(k)$  protocol in which the predicate  $\rho_V$  depends on the whole conversation and some additional random string, can be transformed into an  $AM(k+1)$  protocol in which no such additional string is used: Simply, let the verifier send this random string as its last message. Hence, since we prove our result for any constant-round  $AM$  protocol, we can assume that  $\rho_V$  is deterministic.  $\square$

**Remark 6.3** (*interactive arguments*): We now show how to generalize the above proof of the case  $AM(3)$  in order to prove the same result in the setting of interactive arguments, i.e. "interactive proofs" in which the soundness condition is required only with respect to provers limited to probabilistic polynomial-time computations, possibly getting an auxiliary-input. We have to prove Lemma 6.3 in this setting. Notice that part (2) of the lemma relies on the completeness and zero-knowledge properties of the interactive proof, but these properties are not influenced by the soundness condition. Therefore, this part of the proof automatically holds for interactive arguments. The other part, part (1), relies on the soundness of the interactive proof, thus, a modification is required in the proof to deal with provers having just polynomial power.

In that proof we showed, by contradiction, the existence of infinitely many  $x$ 's not in  $L$  for which a cheating prover can convince the verifier to accept  $x$  with non-negligible probability. The success of this prover was shown by proving, for each such  $x$ , the *existence* of a message  $\alpha_x$  that for non-negligibly many  $\beta$ 's a string  $\gamma$  exists such that  $\rho_V(x, \alpha_x, \beta, \gamma) = ACCEPT$ . In the interactive arguments setting the sole existence of such an  $\alpha_x$  is not sufficient. The limited prover should find in probabilistic polynomial-time this string and the corresponding response  $\gamma$  to the message  $\beta$  sent by  $V$ . We describe such a prover  $P^*$  that uses the simulator  $M$  in order to find the required strings. It begins by choosing  $i \in_R \{1, \dots, t\}$ , and random strings  $R_M, \beta^{(1)}, \dots, \beta^{(i-1)}$ . Then it computes  $\alpha = \alpha_M(x, R_M, \beta^{(1)}, \dots, \beta^{(i-1)})$ , and sends this  $\alpha$  to  $V$ . Once  $V$  responds with  $\beta$ , the prover  $P^*$  chooses  $t-i$  random strings  $\beta^{(i+1)}, \dots, \beta^{(t)}$  and computes (using the simulator  $M$ ) the conversation  $conv_M(x, R_M, \beta^{(1)}, \dots, \beta^{(i-1)}, \beta, \beta^{(i+1)}, \dots, \beta^{(t)})$ , and sends to  $V$  the message  $\gamma$

appearing in this conversation. If the chosen vector is  $i$ -good then this  $\gamma$  convinces  $V$  to accept the conversation. We analyze the probability of such event.

There exists a non-negligible probability that  $P^*$  chooses  $i$ ,  $1 \leq i \leq t$ , for which the number of  $i$ -good vectors is non-negligible (we saw that such an  $i$  exists). On the other hand, the whole vector  $(x, R_M, \beta^{(1)}, \dots, \beta^{(i-1)}, \beta, \beta^{(i+1)}, \dots, \beta^{(t)})$ , is chosen at random (except for  $x$ ): the  $\beta$  component by the verifier (the protocol is Arthur-Merlin!) and the other components by  $P^*$ . Therefore, there is a non-negligible probability that the resultant vector is  $i$ -good, in which case  $V$  accepts  $x$ . This way  $P^*$  works in polynomial-time and has a non-negligible probability to convince  $V$  of accepting  $x$  from what we derive the required contradiction.  $\square$

## 6.2 The case AM(k): Secret Coins Help Zero-Knowledge

In this section we consider constant-round Arthur-Merlin interactive proofs. We show that a language having such an interactive proof which is also black-box simulation zero-knowledge belongs to BPP, thus proving Theorem 6.1. We present this proof based on the proof for the particular case of AM(3) as given in section 6.1. The basic ideas are similar but their implementation is technically more involved in this general case. We highly recommend familiarity with section 6.1 before going through the present section.

**The protocol  $\langle P, V \rangle$ :** Let  $\langle P, V \rangle$  be a  $k$ -round Arthur-Merlin protocol for a language  $L$ . For simplicity of the exposition we make some assumptions on the form of the protocol without restricting the generality of the proof. We consider protocols in which both the first and last messages are sent by the prover. By adding dummy messages any protocol can be converted into one of this form. Notice that in such a protocol, the number of rounds is always an odd number  $k = 2 \cdot m + 1$ . The prover  $P$  sends  $m+1$  messages which we denote by  $\alpha_1, \dots, \alpha_m$ , and  $\gamma$ , respectively. The  $m$  messages by  $V$  are denoted  $\beta_1, \dots, \beta_m$ . The input to the protocol is denoted by  $x$  and its length by  $n$ . The predicate computed by the verifier  $V$  in order to accept or reject the input  $x$  is denoted by  $\rho_V$ , and we assume it to be a deterministic function of the conversation  $\rho_V(x, \alpha_1, \beta_1, \dots, \alpha_m, \beta_m, \gamma)$ . (Our results hold also for interactive proofs in which  $\rho_V$  depends on an additional random string. See Remark 6.2). We need the following technical convention. We assume that all prover messages in the protocol have a form that allows, by only seeing the  $i$ -th message  $\alpha_i$ , to uniquely reconstruct all previous messages sent by the prover during the conversation. This is easily achieved by simple concatenation of previous messages (using a delimiter or some length convention). We also assume the existence of a polynomial  $l(n)$  such that all prover and verifier's messages on an  $n$ -length input have length  $l(n)$  (e.g. using dummy padding). Finally, we let the

verifier  $V$  check whether the received messages conform to the above conventions, and reject the conversation if not.

**The simulation process:** We denote by  $M$  the black-box simulator for the protocol  $\langle P, V \rangle$ . The simulation process consists of several tries by the simulator  $M$ . Each try involves feeding the verifier  $V^*$  (i.e. the black-box representing it) with a value  $y$  as the input to the protocol, and the messages  $\alpha_i$ ,  $1 \leq i \leq m$ , that simulate the messages sent by  $P$ . (Again, we do not care about random coins for  $V^*$ , we just need a simulator that is able to simulate conversations with deterministic verifiers). The simulator  $M$  chooses these arguments, in the successive tries, depending on the random tape  $R_M$  and the responses  $\beta_i$  output by the black-box  $V^*$  during the current and previous tries. After each try the simulator may decide to output a conversation of the form  $(y, \alpha_1, \beta_1, \dots, \alpha_m, \beta_m, \gamma)$  or to perform a new try. We assume that the output conversation has  $y = x$ , i.e. the input component in the conversation corresponds to the actual input being simulated; that the  $\alpha$  messages appearing in the output conversation fit our convention on the form of the prover's messages; and that the simulator explicitly tries the output conversation. Namely, it operates (in one of the tries) the black-box  $V^*$  on input  $x$  and  $\alpha_1, \dots, \alpha_m$  as appearing in the output conversation, and respectively gets as responses of  $V^*$  the strings  $\beta_1, \dots, \beta_m$  also appearing in this conversation. These assumptions are apparently restricting ones since the simulator is allowed to output conversations that are not "legal conversations" between the prover  $P$  and the simulated verifier  $V^*$ . Nevertheless, a simulator that succeeds simulating the  $\langle P, V^* \rangle$  conversations, will output such illegal conversations with only negligible probability (otherwise the simulated conversations can be easily distinguished from the true ones). Finally, we consider, for the sake of simplicity, only simulators that run (strictly) polynomial-time. The necessary changes in the proof for handling the general case in which the simulator runs *expected* polynomial-time are analogous to the ones described in Remark 6.1 for the case  $AM(3)$ . We denote by  $\hat{i}(n)$  a polynomial bounding the number of calls to  $V^*$  tried by  $M$  before outputting a conversation, and put  $t(n) = m \cdot \hat{i}(n)$  (notice that  $t(n)$  constitutes an upper bound on the total number of messages  $\alpha$  tried by  $M$  during the whole simulation).

**The simulator as a subroutine:** Our goal is to present a BPP algorithm for the language  $L$  and we use the simulator  $M$  for achieving it. The way  $M$  is used is similar to the way we used the simulator in the  $AM(3)$  case (see Section 6.1). In the present case, the behavior of the simulator  $M$ , when "interacting" with a verifier  $V^*$ , is determined by the input  $x$  to the protocol, the random tape  $R_M$  and the strings  $\beta$  output by  $V^*$  as responses to the strings fed by  $M$  during the different tries. Also here we define a computational process that uses  $M$  as a subroutine.

Fix an input  $x$  of length  $n$ , a string  $R_M$  and  $t=t(n)$  strings  $\beta^{(1)}, \beta^{(2)}, \dots, \beta^{(t)}$ , each of length  $l(n)$ . Activate  $M$  on input  $x$  with its random tape containing  $R_M$ . For each message  $\alpha$  presented by  $M$ , respond in the following way. (The responses will depend on the strings  $\alpha$ , but not on  $y$ ). If  $\alpha$  is "illegal" then respond with a special "reject-message". By illegal we mean a message  $\alpha$  that does not fit our above conventions on the form of the prover's messages. For legal  $\alpha$ 's we respond (impersonating a black-box verifier) with one of the  $\beta$ 's from the above list  $\beta^{(1)}, \dots, \beta^{(t)}$  according to the following rule. If the same  $\alpha$  was previously presented by  $M$  (i.e. during a previous try), respond with the same  $\beta$  as in that case. If  $\alpha$  is the  $i$ -th *different* (legal) string presented by  $M$  since the beginning of the simulation then respond with  $\beta^{(i)}$ . We denote the  $i$ -th different  $\alpha$  by  $\alpha^{(i)}$ . Clearly,  $\alpha^{(i)}$  is uniquely determined by  $x, R_M$  and the  $i-1$  strings  $\beta^{(1)}, \dots, \beta^{(i-1)}$ . That is, there exists a deterministic function  $\alpha_M$  such that  $\alpha^{(i)} = \alpha_M(x, R_M, \beta^{(1)}, \dots, \beta^{(i-1)})$ . We denote by  $\text{conv}_M(x, R_M, \beta^{(1)}, \dots, \beta^{(t)}) = (y, \alpha_1, \beta_1, \dots, \alpha_m, \beta_m, \gamma)$  the conversation output by the simulator  $M$  when activated with these parameters (notice that  $t$  strings  $\beta^{(i)}$  always suffice for answering all tries of  $M$ ). By our convention on the simulator  $M$  and on the form of the prover's messages it follows that there exists a sequence of indices  $1 \leq i_1 < i_2 < \dots < i_m \leq t$  such that for each  $\alpha_j, \beta_j, j=1, \dots, m$ , appearing in the output conversation,  $\alpha_j = \alpha^{(i_j)}$  and  $\beta_j = \beta^{(i_j)}$ . This is true since the simulator always outputs a conversation which was explicitly generated in one of its tries. The increasing property of the sequence of indices  $i_j$  is enforced by the special form of the "legal" messages  $\alpha$ , namely, by the fact that we respond to message  $\alpha_j$  only if we had previously responded to the messages  $\alpha_1, \dots, \alpha_{j-1}$ . In the present setting we use the following definition of  $M$ -good vectors.

Definition: We say that a vector  $(x, R_M, \beta^{(1)}, \dots, \beta^{(t)})$  is  $M$ -good if  $\text{conv}_M(x, R_M, \beta^{(1)}, \dots, \beta^{(t)})$  is an accepting conversation for the (honest) verifier  $V$ . We say that  $(x, R_M, \beta^{(1)}, \dots, \beta^{(t)})$  is  $(i_1, i_2, \dots, i_m)$ -good if it is  $M$ -good and the corresponding conversation has  $\alpha_j = \alpha^{(i_j)}$  and  $\beta_j = \beta^{(i_j)}$ , for  $j = 1, \dots, m$ .

The following Lemma is analogous to Lemma 6.3.

**Lemma 6.4:** Let  $k=2 \cdot m+1$  be a constant and let  $\langle P, V \rangle$  be a  $k$ -round Arthur-Merlin protocol for a language  $L$ . Suppose  $\langle P, V \rangle$  is black-box simulation zero-knowledge, and let  $M$  be a black-box simulator as above. Then,

- (1) For strings  $x$  outside  $L$ , only a negligible portion of the vectors  $(x, R_M, \beta^{(1)}, \dots, \beta^{(t)})$  are  $M$ -good.
- (2) For strings  $x$  in  $L$  there exists a non-negligible portion of the vectors  $(x, R_M, \beta^{(1)}, \dots, \beta^{(t)})$  that are  $M$ -good.

(This non-negligible portion is at least one half of the completeness probability of

the protocol  $\langle P, V \rangle$ , i.e. the probability that  $P$  convinces  $V$  to accept  $x$ ).

**Proof of Theorem 6.1:** Using Lemma 6.4 we get that the algorithm described in the proof of Theorem 6.1 for the special case of AM(3) (see section 6.1) is a BPP algorithm for the language  $L$ . ■

**Proof of Lemma 6.4:** This proof is essentially analogous to the proof of Lemma 6.3, although some delicate modifications are required.

Part (1): Assume that the portion of  $M$ -good vectors  $(x, R, \beta^{(1)}, \dots, \beta^{(t)})$  for  $x$ 's not in  $L$  is not negligible. This means that there exist infinitely many  $x \notin L$  for which the portion of  $M$ -good vectors is non-negligible. Observe that there are only polynomially many different sequences  $1 \leq i_1 < i_2 < \dots < i_m \leq t$  (i.e.  $\binom{t(n)}{m}$ , and  $m$  is a constant), and then for each  $x$  as above, there exists a sequence  $(i_1, i_2, \dots, i_m)$  for which non-negligibly many vectors  $(x, R_M, \beta^{(1)}, \dots, \beta^{(t)})$  are  $(i_1, i_2, \dots, i_m)$ -good. Next, we describe a prover  $P^*$  which convinces the (honest) verifier  $V$  to accept any of the above inputs  $x \notin L$  with non-negligible probability, thus contradicting the soundness condition of the protocol  $\langle P, V \rangle$ .

The prover  $P^*$  begins by choosing a sequence  $(i_1, i_2, \dots, i_m)$  at random. Then, it chooses random strings  $R_M, \beta^{(1)}, \dots, \beta^{(i_1-1)}$  and uses them to compute  $\alpha_1 = \alpha_M(x, R_M, \beta^{(1)}, \dots, \beta^{(i_1-1)})$ . It sends  $\alpha_1$  to  $V$  and receives back the response  $\beta_1$ . Now  $P^*$  chooses random  $\beta^{(i_1+1)}, \dots, \beta^{(i_2-1)}$  and computes  $\alpha_2 = \alpha_M(x, R_M, \beta^{(1)}, \dots, \beta^{(i_1-1)}, \beta_1, \beta^{(i_1+1)}, \dots, \beta^{(i_2-1)})$ . After receiving the response  $\beta_2$  from the verifier,  $P^*$  selects new random strings  $\beta^{(i_2+1)}, \dots, \beta^{(i_3-1)}$ , and computes  $\alpha_3 = \alpha_M(x, R_M, \beta^{(1)}, \dots, \beta^{(i_1-1)}, \beta_1, \beta^{(i_1+1)}, \dots, \beta^{(i_2-1)}, \beta_2, \beta^{(i_2+1)}, \dots, \beta^{(i_3-1)})$ . This process continues until all messages  $\alpha_i, \beta_i, 1 \leq i \leq m$ , are computed and exchanged. In case that the resultant vector  $(x, R_M, \beta^{(1)}, \dots, \beta^{(i_1-1)}, \beta_1, \beta^{(i_1+1)}, \dots, \beta^{(i_2-1)}, \beta_2, \dots, \beta^{(t)})$  is  $(i_1, i_2, \dots, i_m)$ -good then computing the function  $conv_M$  on this vector results in an accepting (for  $V$ ) conversation  $(x, \alpha_1, \beta_1, \dots, \alpha_m, \beta_m, \gamma)$  (with  $\alpha_i, \beta_i$ , as defined above). But then by sending this  $\gamma$  the prover  $P^*$  convinces  $V$  to accept. The probability that this happens equals the probability that the above vector  $(x, R_M, \beta^{(1)}, \dots, \beta^{(i_1-1)}, \beta_1, \beta^{(i_1+1)}, \dots, \beta^{(i_2-1)}, \beta_2, \dots, \beta^{(t)})$  is  $(i_1, i_2, \dots, i_m)$ -good. Since this sequence of indices and all the vector components (excluding  $x$ ) are chosen at random (recall that  $V$  chooses its messages,  $\beta_1, \dots, \beta_m$ , at random!) then this probability is non-negligible.

Part (2): The proof of this part is analogous to the corresponding proof in Lemma 6.3. We use a set  $H_n$  of  $t(n)$ -independent hash functions ( $t(n)$  as defined in this section) to define a family of verifiers  $V_h^*$ . For all  $h \in H_n$ , the verifier  $V_h^*$  responds to a legal message  $\alpha$  sent by the prover with  $h(\alpha)$ , and with a rejection message if  $\alpha$  is illegal. The

statements for Claims 1 and 2 remain the same, as well as the proof of Claim 2. The proof of Claim 1 needs a more delicate argument, as follows. As in the AM(3) case we consider the interaction between the prover  $P$  and a verifier  $V_h^*$ , but now this interaction generates a conversation of the form  $(x, \alpha_1, \beta_1, \dots, \alpha_m, \beta_m, \gamma)$ . In particular, for each  $h$  and random tape  $R_P$  for  $P$  a unique sequence of messages  $\beta_1, \dots, \beta_m$  (the responses of  $V_h^*$ ) is determined. We have to show that for every tape  $R_P$  all sequences  $\beta_1, \dots, \beta_m$  are equiprobable for  $h \in_R H_n$ . The proof of this property uses a similar argument as the proof of claim 2: observe that the pair  $R_P$  and  $h$  generates the responses  $\beta_1, \dots, \beta_m$  if and only if for every  $i$ ,  $1 \leq i \leq m$ ,  $h(\alpha_P(x, R_P, \beta_1, \dots, \beta_{i-1})) = \beta_i$ . (Here  $\alpha_P$  stands for the function computed by  $P$  in order to determine its next message  $\alpha$ ). Thus, the probability (for  $h \in_R H_n$ ) that a given sequence  $\beta_1, \dots, \beta_m$  is generated is as the probability that for every  $i$ ,  $1 \leq i \leq m$ ,  $h$  maps  $\alpha_P(x, R_P, \beta_1, \dots, \beta_{i-1})$  into  $\beta_i$ . Since the functions  $H_n$  are  $m$ -independent (by definition they are  $t(n)$ -independent, but  $m \leq t(n)$ ), and the messages  $\alpha_1, \dots, \alpha_m$  output by  $P$  are all different by convention, we get that the latter probability is the same for every sequence  $\beta_1, \dots, \beta_m$ .

From this property of the pairs  $R_P$  and  $h$  we conclude that the the probability that  $P$  and  $V_h^*$  (for  $h \in_R H_n$ ) output an accepting conversation is exactly the same as the probability that  $P$  and the honest  $V$  output such a conversation.

The rest of the proof follows as in Claim 1 of Lemma 6.3. ■

**Remark 6.4:** Notice that the prover  $P^*$  described in the proof of part (1) of Lemma 6.4 is a polynomial-time prover. The other parts of the proof of Theorem 6.1 also hold for such provers and then we get that our result remains valid also in the setting of interactive arguments.

### 6.3 The case IP(3)

In the setting of general interactive proofs the (honest) verifier is not restricted to choose all its messages at random, but can compute them based on the input  $x$ , a random ("secret") string  $r$  and the previous messages of the prover. In the case of 3 rounds this means that the only message sent by  $V$  during the protocol is computed by means of a (deterministic) function  $\beta_V(x, r, \alpha)$ , where  $\alpha$  is the first message sent by  $P$ . Also, in this case  $V$  accepts or rejects a conversation based on a predicate  $\rho_V(x, r, \alpha, \gamma)$  ( $\gamma$  is the last message sent by  $P$ ).

Here we outline the proof of Theorem 6.2, based on the proof presented in section 6.1 for the AM(3) case.

**Proof of Theorem 6.2 (outline):** Let  $L$  be a language having a 3-round interactive proof which is black-box simulation zero-knowledge. Let  $\langle P, V \rangle$  be such a protocol and let  $M$  be the corresponding black-box simulator. The simulation process consists of several tries, in each of them the simulator feeds the black-box  $V^*$  with arguments  $y$  (the input) and  $\alpha$  (the prover's message), and gets an answer  $\beta$  from  $V^*$ . (Again, it suffices to consider a simulator just able to simulate conversations with deterministic verifiers, so this simulator does not feed  $V^*$  with a random tape). We assume the same conventions on the simulator as the ones described in section 6.1 for the proof of the AM(3) case:

- The simulator always outputs a conversation of the form  $(x, \alpha, \beta, \gamma)$ , where  $x$  and  $\alpha$  are fed into the black-box  $V^*$  in one of the simulator tries, and  $\beta$  is the response of  $V^*$  to these arguments.
- The simulator runs in strictly polynomial-time. In particular,  $t(n)$  stands for the polynomial bound on the number of tries made by  $M$  on inputs of length  $n$  during the simulation process (the case of expected polynomial-time simulators is handled exactly as in Remark 6.1).

The main modification with respect to the proof of the AM(3) case is in the way we use the simulator  $M$  as a subroutine for constructing the BPP algorithm for the language  $L$ . Recall that the whole simulation process is completely determined by the input to the protocol,  $x$ , the contents of  $M$ 's random tape,  $R_M$ , and the responses by the verifier. This was true for the AM(3) case and remains true here. In the former case we used  $M$  as a subroutine by feeding it with  $x$  and a randomly chosen string  $R_M$ . Then, we used  $t = t(n)$  random strings  $\beta^{(1)}, \dots, \beta^{(t)}$  as the responses of the virtual verifier. In the present case we choose a string  $R_M$  as before, and  $t$  random strings denoted  $r^{(1)}, \dots, r^{(t)}$ , each of length  $l(n)$ , where  $l(n)$  is a (polynomial) bound on the number of random bits used by the (honest) verifier in the IP(3) protocol  $\langle P, V \rangle$ . The idea is to use these strings as the random coins of the virtual verifier for responding  $M$ 's tries. More precisely, for each try by the simulator, consisting of an input  $y$  to the protocol and a message  $\alpha$ , we compute  $\beta = \beta_V(y, r^{(i)}, \alpha)$ , and feed it into  $M$  as the verifier's response to  $\alpha$ . For each new try we use a new  $r^{(i)}$  (in increasing order of  $i$ ), except in the case in which the present  $\alpha$  was also presented in a previous try. If so, we use same  $r^{(i)}$  as in that case.

Note that a unique conversation is determined by  $x$ ,  $R_M$  and the  $t$  strings  $r^{(1)}, \dots, r^{(t)}$ . Thus, as in the case AM(3), we can define  $\text{conv}_M(x, R_M, r^{(1)}, \dots, r^{(t)})$  to be the conversation output by  $M$  when the described process is finished. Also we denote by  $\alpha^{(i)}$  the  $i$ -th different  $\alpha$  output by  $M$  during the simulation. Clearly,  $\alpha^{(i)}$  is uniquely determined by  $x, R_M$ , and the strings  $r^{(1)}, \dots, r^{(i-1)}$ , thus we denote  $\alpha^{(i)} = \alpha_M(x, R_M, r^{(1)}, \dots, r^{(i-1)})$ .

By our convention on  $M$ , if  $\text{conv}(x, R_M, r^{(1)}, \dots, r^{(t)}) = (x, \alpha, \beta, \gamma)$  then  $M$  explicitly tried the

arguments  $x$  and  $\alpha$  during the simulation, and got as response the string  $\beta$ . This means that there exists (at least one)  $i$ ,  $1 \leq i \leq t$ , such that  $\beta = \beta_V(x, r^{(i)}, \alpha)$ . This fact is used in the following definition.

**Definition:** We say that a vector  $(x, R_M, r^{(1)}, \dots, r^{(t)})$  is *M-good* if  $\text{conv}(x, R_M, r^{(1)}, \dots, r^{(t)}) = (x, \alpha, \beta, \gamma)$  and  $\rho_V(x, r^{(i)}, \alpha, \gamma) = \text{ACCEPT}$ , where  $i$  is minimal for which  $\beta = \beta_V(x, r^{(i)}, \alpha)$ . According to this value of  $i$ , we call the conversation  $(M, i)$ -good (or *i-good* for short).

Using this re-definition of the notion of *M-goodness*, Lemma 6.3 of section 6.1 also holds in the present (IP(3)) case, by just changing in the formulation of the lemma the  $\beta^{(i)}$  notation by  $r^{(i)}$ . Theorem 6.2 then follows by using the BPP algorithm as described in the proof of the AM(3) case. For the proof of Lemma 6.3 in the present case we note the following simple modifications. In the proof of part (1) we use the same reasoning as in the corresponding proof in section 6.1 but applied to the strings  $r^{(i)}$  instead of  $\beta^{(i)}$ . We note that the soundness probability of the protocol is now defined over the random coins used by  $V$ , i.e. over the choices  $r^{(i)}$ . For the proof of the other part of the lemma we slightly modify the definition of the verifiers  $V_h^*$ . We still use the same family of hash functions, but the verifier  $V_h^*$  works as follows: on message  $\alpha$  sent by the prover,  $V_h^*$  responds with  $\beta = \beta_V(x, h(\alpha), \alpha)$ , i.e. it computes  $\beta$  as the honest verifier does, but using  $h(\alpha)$  as the random coins of  $V$ . The rest of the proof (including Claims 1 and 2) remains essentially unchanged (up to the replacement of "responses  $\beta^{(i)}$ " by "random coins  $r^{(i)}$ "). ■

**Remark 6.5:** As in the previous cases also the IP(3) case extends to the setting of interactive arguments. The modifications in the proof are analogous to the ones described in Remark 6.3.

## 7. CONCLUDING REMARKS

Although the results presented in this paper are negative in nature, we believe that they have played a positive role in the development of the field.

We believe that sequential composition is a fundamental requirement of zero-knowledge protocols. It is analogous to requiring that adding two algebraic expressions, each evaluating to zero, yields an expression which evaluates to zero. Furthermore, sequential composition is required when using zero-knowledge proofs as tools in the design of cryptographic protocols (an application which is the primary motivation of zero-knowledge). *The fact that the original formulation of zero-knowledge is not closed under sequential composition establishes the importance of augmenting this formulation by an auxiliary input* (cf. [GO, Ore, TW, Gol]). It should be stressed, of course, that all known zero-knowledge proofs satisfy also the augmented formulation.

Parallel composition is the key to improving the efficiency (in terms of number of rounds) of zero-knowledge protocols, but we do not believe that it is a fundamental requirement. Carrying the analogy of the previous paragraph, one cannot require that “interleaving” two expressions (each evaluating to zero) yields an expression which evaluates to zero. *The fact that all known formulations of (computational) zero-knowledge are not closed under parallel composition motivates the introduction of weaker notions such as witness indistinguishability [FS2] which suffice for many applications.* Namely, instead of strengthening the hypothesis of the alleged “Parallel Composition Theorem” (as done in the case of Sequential Composition), one relaxes the conclusion of the “Parallel Composition Theorem” (and this weaker conclusion turns to suffice in many applications).

The fact that (“non-trivial”) black-box zero-knowledge proofs cannot be both of AM type and of constant number of rounds establishes the importance of “private coins” in the design of constant-round zero-knowledge proofs. In other words, in the process of such proofs, the verifier must “commit” (and later “decommit”) to some pieces of information. In fact, such commitments are the core of the constant-round zero-knowledge proofs (and arguments) for any language in *NP* presented in [BCY, FS1, GK] (relying on various reasonable intractability assumptions) and in the (unconditional) zero-knowledge proof for Graph Isomorphism presented in [BMO1].

## ACKNOWLEDGEMENTS

Silvio Micali was one of the only to strongly object the “intuition” that the parallel versions of the interactive proof systems for Quadratic Residuosity, Graph Isomorphism, and all languages in *NP*, are zero-knowledge. The results in this paper are rooted in this clear vision of Silvio. We are grateful to him for that.

## APPENDIX: Proof of existence of P/poly-evasive pseudorandom ensembles

In this appendix we present the proof of Theorem 3.2.

**Theorem 3.2.** There exists a P/poly-evasive ensemble  $\mathcal{S}^{(1)}, \mathcal{S}^{(2)}, \dots$  with  $Q(n) = 4n$ , such that for every  $n$ , each  $S_i^{(n)}$  is a  $(2^{n/4}, 2^{-n/4})$ -pseudorandom set of cardinality  $2^n$ . Furthermore, there exists a Turing machine which on input  $1^n$  outputs the collection  $\mathcal{S}^{(n)}$ .

**Proof:** For any integer  $n$ , we denote by  $\mathbf{R}^{(n)}$  the collection of sets  $S \subseteq \{0,1\}^{4n}$  of cardinality  $2^n$  which are  $(2^{n/4}, 2^{-n/4})$ -pseudorandom; and by  $\mathbf{C}^{(n)}$  the set of (deterministic) circuits of size  $2^{n/4}$  having  $n$  inputs and  $4n$  outputs.

We prove the theorem by showing, for any large enough  $n$ , the existence of  $2^n$  sets  $S_1, \dots, S_{2^n}$  from  $\mathbf{R}^{(n)}$  such that for any circuit  $C \in \mathbf{C}^{(n)}$ , and  $i \in_R \{1, \dots, 2^n\}$ ,  $\text{Prob}(C(i) \in S_i) < 2^{-n/4}$ . Denoting this collection of  $2^n$  sets by  $\mathcal{S}^{(n)}$ , we get that the resultant sequence  $\mathcal{S}^{(1)}, \mathcal{S}^{(2)}, \dots$  is a P/poly-evasive ensemble that satisfies the conditions of Theorem 3.2. We stress that considering only deterministic circuits does not restrict the generality, since we can wire in such a circuit a sequence of "random coins" that maximizes the probability  $\text{Prob}(C(i) \in S_i)$ .

We turn to show the existence of a collection of sets as described above. We do it by proving that there exists a positive probability to randomly choose  $2^n$  sets  $S_1, \dots, S_{2^n}$  from  $\mathbf{R}^{(n)}$  with the above evasivity property.

For a fixed  $C \in \mathbf{C}^{(n)}$  and a fixed  $i, 1 \leq i \leq 2^n$ , consider the probability, denoted  $\text{Prob}_S(C(i) \in S)$ , that the element  $C(i)$  belongs to the  $S$ , for  $S$  uniformly chosen over all subsets of  $\{0,1\}^{4n}$  of size  $2^n$ . Clearly,

$$\text{Prob}(C(i) \in S) = 1 - \frac{\binom{2^{4n}-1}{2^n}}{\binom{2^{4n}}{2^n}} = \frac{2^n}{2^{4n}} < \frac{1}{2^{2n}}.$$

We call a set  $S \subseteq \{0,1\}^{4n}$ ,  $|S| = 2^n$ ,  $C$ -bad if there exists some  $i, 1 \leq i \leq 2^n$  such that  $C(i) \in S$ . Fixing a circuit  $C$ , we have that for  $S$  uniformly chosen over all subsets of  $\{0,1\}^{4n}$  of size  $2^n$ ,

$$\text{Prob}_S(S \text{ is } C\text{-bad}) \leq \sum_{i=1}^{2^n} \text{Prob}_S(C(i) \in S) < 2^n 2^{-2n} = 2^{-n}.$$

In [GK] it is proven that the measure of  $\mathbf{R}^{(n)}$  (i.e. the proportion of sets  $S$  which are  $(2^{n/4}, 2^{-n/4})$ -pseudorandom) is at least  $1 - 2^{-2^{n/4}}$ . Therefore, for each circuit  $C \in \mathbf{C}^{(n)}$  the probability, hereafter denoted as  $p_C$ , to uniformly choose from  $\mathbf{R}^{(n)}$  a set  $S$  which is  $C$ -bad is

$$p_C = \text{Prob}_S(S \text{ is } C\text{-bad} \mid S \in \mathbf{R}^{(n)}) < \frac{2^{-n}}{1 - 2^{-2^{n/4}}}$$

We now proceed to compute the probability that for a fixed circuit  $C \in \mathcal{C}^{(n)}$ , a collection of  $2^n$  randomly chosen sets from  $\mathbf{R}^{(n)}$  contain a significant portion of  $C$ -bad sets. We define as "significant" a fraction  $p_C + \delta_n$ . (The quantity  $\delta_n$  will be determined later). Let  $\rho$  be a random variable assuming as its value the fraction of  $C$ -bad sets on a random sample of  $2^n$  sets from  $\mathbf{R}^{(n)}$ . Clearly, the expected value of  $\rho$  is  $p_C$ . Using Hoeffding's inequality [Hoe] (see also [GK]) we get that

$$\text{Prob}(\rho \geq p_C + \delta_n) \leq e^{-2 \cdot 2^n \delta_n^2}.$$

i.e. this quantity bounds the probability of choosing at random  $2^n$  sets from  $\mathbf{R}^{(n)}$  among which the fraction of  $C$ -bad sets is larger than  $p_C + \delta_n$ .

Recall that we are interested to choose  $2^n$  sets that are evasive for *all* the circuits  $C \in \mathcal{C}^{(n)}$ . That is, we require that for *any*  $C$ , the number of  $C$ -bad sets among the  $2^n$  sets we choose is negligible. In order to bound the probability that  $2^n$  randomly selected sets *do not* satisfy this condition, we multiply the above probability, computed for a single circuit, by the total number of circuits in  $\mathcal{C}^{(n)}$  which is at most  $2^{(2^{n/4})^2} = 2^{2^{n/2}}$ . Putting  $\delta_n = \frac{2^{-n/4}}{\sqrt{2}}$  we get

$$2^{2^{n/2}} \cdot e^{-2 \cdot 2^n \delta_n^2} = 2^{2^{n/2}} \cdot e^{-2 \cdot 2^n \cdot 2^{-\frac{n}{2}-1}} = 2^{2^{n/2}} \cdot e^{-2^{n/2}} < 1.$$

We conclude that there exists a positive probability that  $2^n$  sets  $S_1, \dots, S_{2^n}$  chosen at random from  $\mathbf{R}^{(n)}$  have the property that for any circuit  $C \in \mathcal{C}^{(n)}$  the fraction of  $C$ -bad sets among  $S_1, \dots, S_{2^n}$  is less than  $p_C + \delta_n$ . Therefore, such a collection of sets does exist.

Finally, we bound, for this fixed collection  $S_1, \dots, S_{2^n}$ , and for any circuit  $C \in \mathcal{C}^{(n)}$ , the probability  $\text{Prob}_i(C(i) \in S_i)$ , for  $i$  randomly chosen from  $\{1, \dots, 2^n\}$ . We have

$$\begin{aligned} \text{Prob}_i(C(i) \in S_i) &= \text{Prob}_i(C(i) \in S_i \mid S_i \text{ is } C\text{-bad}) \cdot \text{Prob}_i(S_i \text{ is } C\text{-bad}) \\ &\quad + \text{Prob}_i(C(i) \in S_i \mid S_i \text{ is not } C\text{-bad}) \cdot \text{Prob}_i(S_i \text{ is not } C\text{-bad}) \\ &\leq 1 \cdot (p_C + \delta_n) + 0 < \frac{2^{-n}}{1 - 2^{-n/4}} + \frac{2^{-n/4}}{\sqrt{2}} < 2^{-n/4} \end{aligned}$$

Therefore, we have shown for every circuit  $C$  of size  $2^{n/4}$  that  $\text{Prob}_i(C(i) \in S_i) < 2^{-n/4}$ , thus proving the required properties of the sets  $S_1, \dots, S_{2^n}$ .

Such a collection can be generated by a Turing machine by considering all possible collections  $\{S_1, \dots, S_{2^n}\}$  and checking whether they evade all the circuits in the set  $\mathcal{C}^{(n)}$ .
